Handbook of Pigeonpea Diseases
Information Bulletin no. 42
International Crops Research Institute for the Semi-Arid Tropics
Abstract

Pigeonpea (Cajanus cajan (L.) Millsp.) is one of the most important grain legume components of subsistence farming systems in the semi-arid tropics. Many fungi, viruses, nematodes, bacteria, and mycoplasma-like organisms attack pigeonpea, but only a few of these are important constraints to pigeonpea production. This bulletin provides information on the causal agents, distribution, economic importance, symptoms, epidemiology, and management of major diseases of pigeonpea. The text is supplemented with color photographs of disease symptoms and a diagnostic key is included to facilitate identification. Information is provided on control measures that include the use of resistant varieties, cultural practices, and chemicals. Supporting literature on the major diseases is listed.

Résumé

Manuel des maladies du pois d'Angole. Le pois d'Angole [Cajanus cajan (L.) Millsp.] est l'une des légumineuses à grain les plus importantes des systèmes d'agriculture de subsistance au sein des régions tropicales semi-arides. Plusieurs champignons, virus, nématodes, bactéries et organismes de type mycoplasma attaquent le pois d'Angole, mais seul quelques-uns constituent des contraintes majeures à la production du pois d'Angole. Ce bulletin offre des informations sur les agents causaux, la répartition, l'importance économique, les symptômes, l'épidémiologie ainsi que la lutte contre les maladies importantes de cette culture. Le texte est accompagné de photographies en couleur des symptômes de maladies et une clé diagnostique permet leur identification. Des informations sont fournies sur les moyens de lutte y compris l'emploi de variétés résistantes, de pratiques culturales et de produits chimiques. Une bibliographie de la documentation de base sur les maladies importantes du pois d'Angole est prévue.

Subject Index 60
Introduction

Pigeonpea (*Cajanus cajan* (L) Millsp.) is an important grain legume crop of rainfed agriculture in the semi-arid tropics. The Indian sub-continent, eastern Africa, and central America, in that order, are the world's three main pigeonpea-producing regions. Pigeonpea is cultivated in more than 25 tropical and sub-tropical countries, either as a sole crop or intermixed with such cereals as sorghum (*Sorghum bicolor* (L.) Moench), pearl millet (*Pennisetum glaucum* (L.) R. Br.), or maize (*Zea mays* L.), or with legumes, e.g., groundnut (*Arachis hypogaea* L.). Being a legume, pigeonpea enriches the soil through symbiotic nitrogen fixation. A short-day plant with a deep root system, pigeonpea tolerates drought, but is highly sensitive to waterlogging. The crop has many uses; fresh pigeon peas are eaten as a vegetable, the grain is cooked and eaten as *dhal* (dry split cotyledons), the wood is used as fuel, and the leaves and husks provide livestock feed.

The crop is cultivated on marginal lands by resource-poor farmers, who commonly grow traditional medium- and long-duration (5-11 months) landraces. Short-duration pigeonpeas (3-4 months) suitable for multiple cropping have recently been developed. Traditionally, the use of such inputs as fertilizers, weeding, irrigation, and pesticides are minimal, so present yield levels are low (average = 700 kg ha\(^{-1}\)). Greater attention is now being given to managing the crop because it is in high demand at remunerative prices. There is also a trend away from traditional intercropping to sole cropping.

Diseases are major biological constraints to production and more than 60 pathogens including fungi, bacteria, viruses, mycoplasma, and nematodes can infect pigeonpeas. Fortunately, only a few of them cause economic losses. Of these, sterility mosaic and witches' broom are region-specific, whereas others such as fusarium wilt are widespread across regions.
This handbook has been prepared to assist in field diagnosis of pigeonpea diseases. The diseases are grouped according to the kind of damage they cause. In addition to symptomatology, information on distribution, economic importance, epidemiology, and control measures is included to make the handbook more useful to growers, scientists, and extension practitioners.
Diseases that Kill the Plant

This Section deals with several diseases caused by fungi, one caused by a bacterium, and one abiotic stress—waterlogging—that commonly result in death of plants.

Collar Rot

*Sclerotium rolfsii* Saccardo

**Distribution.** India, Pakistan, Puerto Rico, Sri Lanka, Trinidad and Tobago, USA, and Venezuela.

**Economic importance.** A minor disease that can cause severe losses when undecomposed organic matter is left on the surface of seedbeds. Pigeonpea following cereal crops such as sorghum is likely to be infected if stubbles have not been cleared from the field.

**Epidemiology.** Temperatures of about 30°C and soil moisture at sowing predispose seedlings to infection. In India the disease is more of a problem in early-sown (June) than in later-sown crops.

**Symptoms.** A seedling disease that usually appears within a month of sowing, when patches of dead seedlings at the primary leaf stage are seen, scattered over the field (Fig. 1). The seedlings may turn slightly chlorotic before they die. The confirmatory symptom is rotting in the collar region that is covered with white mycelial growth; this differentiates collar rot from other seedling diseases caused by *Fusarium*, *Rhizoctonia*, or *Pythium*. Seedlings affected by collar rot can be uprooted easily, but the lower part of their root usually remains in soil. Sometimes white or brown sclerotial bodies of the fungus can be found attached to the collar region of a dead seedling or in the soil around it.
Phytophthora Blight

Phytophthora drechsleri Tucker f. sp. cajani
(Mahendra Pal, Grewal & Sarbhoy) Kannaiyan, Ribeiro, Erwin & Nene

Economic importance. A devastating disease that kills young (1-7 week-old) plants, leaving large gaps in plant stands. Yield losses are usually higher in short-duration pigeonpeas than in medium- and long-duration types.

Epidemiology. The disease is soilborne. The fungus survives as chlamydospores, oospores, and dormant mycelium in soil and on infected plant debris. Cloudy weather and drizzling rain with temperatures around 25°C favor infection, that requires continuous leaf wetness for 8 hours to occur. Pigeonpeas gradually develop tolerance to the disease as they grow older and are not infected after they are 60 days old. The disease is more common on Alfisols than on Vertisols, and appears first in low-lying areas of fields where water temporarily stagnates. The thick canopy of short-duration types occasioned by close spacing (30 x 10 cm), and their higher genetic susceptibility, seem to encourage blight build-up. Warm and humid weather following infection results in rapid disease development and plant death. Wind and rain help to disseminate zoospores and by damaging the plant, facilitate infection. Cajanus scarabaeoides var. scarabaeoides, a wild relative of pigeonpea is also a host of the blight pathogen.

Symptoms. Phytophthora blight resembles damping off disease in that it causes seedlings to die suddenly (Fig. 2). Infected plants have water-soaked lesions on their leaves (Fig. 3) and brown to black, slightly sunken lesions on their stems and petioles (Fig. 4). Infected
leaves lose turgidity, and become desiccated. Lesions girdle the affected main stems or branches which break at this point and the foliage above the lesion dries up (Fig. 5). When conditions favor the pathogen, it is common for many plants to die (Fig. 6). Pigeonpea plants that are infected by blight, but not killed often produce large galls on their stems especially at the edges of the lesions (Fig. 7). The pathogen infects the foliage and stems but not the root system.

**Fusarium Wilt**

*Fusarium udum* Butler

**Distribution.** Bangladesh, Ghana, Grenada, India, Indonesia, Kenya, Malawi, Mauritius, Myanmar (Burma), Nepal, Nevis, Tanzania, Thailand, Trinidad and Tobago, Uganda, and Venezuela.

**Economic importance.** The annual losses due to wilt have been estimated at US $ 71 million in India and US $ 5 million in eastern Africa.

**Epidemiology.** The disease is seed and soilborne. The fungus can survive on infected plant debris in the soil for about 3 years. Wilt symptoms usually appear when plants are flowering and podding, but sometimes occur earlier when plants are 1-2 months old. Disease incidence is more severe on Vertisols than on Alfisols. Early sowing, good weed management, and good crop growth encourage wilt development. Long- and medium-duration types suffer more from wilt than short-duration types. Ratooning predisposes the plant to wilt. Pigeonpeas intercropped with sorghum are less attacked by wilt than sole-cropped plants.
Symptoms. Patches of dead plants in the field when the crop is flowering or podding are the first indication of wilt (Fig. 8). The most characteristic symptom is a purple band extending upwards from the base of the main stem (Fig. 9). This band is more easily seen in pigeon-peas with green stems than in those with colored stems. Partial wilting of the plant is a definite indication of fusarium wilt, and distinguishes this disease from termite damage, drought, and phytophthora blight that all kill the whole plant. Partial wilting is associated with lateral root infection, while total wilt is due to tap root infection.

The other characteristic symptom of wilt is browning of the stem tissue in the region of the purple band (Fig. 10) and browning or blackening of the xylem, visible when the main stem or primary branches are split open (Fig. 11). The intensity of browning or blackening decreases from the base to the tip of the plant. Sometimes, branches (especially lower ones) dry, even if there is no band on the main stem. These branches have die-back symptoms with a purple band extending from tip downwards, and intensive internal xylem blackening (Fig. 12). When young plants (1-2 months old) die from wilt, they may not show the purple band symptom, but have obvious internal browning and blackening. Plants infected by *F. udum* also exhibit a series of leaf symptoms before they die, including loss of leaf turgidity, interveinal clearing, and chlorosis to bright yellow.
Dry Root Rot

Macrophomina Stem Canker

*Rhizoctonia bataticola* (Taub.) Butler

*Macrophomina phaseolina* (Tassi) Goidanich

**Distribution.** India, Jamaica, Myanmar (Burma), Nepal, Sri Lanka, and Trinidad and Tobago.

**Epidemiology.** A serious problem in late-sown or summer crops and in perennial or ratooned pigeonpeas. The disease also affects short-duration pigeonpeas sown in the rainy season. Hot (30°C and above) and dry weather encourage disease development, that is more prevalent on Vertisols than on Alfisols. Rain after a prolonged dry spell predisposes plants to the disease. Crops are more susceptible in the reproductive stage than in the vegetative stage.

**Symptoms.** Infected plants suddenly and prematurely dry up (Fig. 13). When such plants are uprooted their roots are rotten and shredded (Fig. 14). The finer roots are mainly affected and have dark, blackened streaks underneath their bark with evident dark sclerotial bodies (Fig. 14). Such roots are brittle and break when touched. Under hot, humid conditions root rotting extends to the base of the stem (Fig. 15). Early symptoms on stems and branches are spindle-shaped lesions (Fig. 16) with light gray centers and brown margins with scattered pycnidal bodies (Fig. 17, x200). The lesions coalesce and cause the branches or whole plants to dry up and die.
Phoma Stem Canker

*Phoma Cajani* (Rangel) Khune & Kapoor

**Distribution.** Brazil and India.

**Symptoms.** Normally seen at advanced stages of plant growth. Initial symptoms on stems appear as lesions with gray centers and dark brown margins. The lesions contain pycnidia. As the disease progresses lesions coalesce and girdle the stem, and then develop into large swollen cankers (Fig. 18) leading to the premature death of the plant.

Anthracnose

*Colletotrichum cajani* Rangel

*Colletotrichum graminicola* (Ces.) Wilson

**Distribution.** Brazil, India, Puerto Rico and USA (Hawaii).

**Symptoms.** A minor stem disease that appears as irregular brown to grayish stem lesions containing dark scattered acervuli (Fig. 19). Severe infection leads to drying and death of infected branches. Minute spots with dark margins and gray centers scattered with acervuli are also common on the leaves and pods of infected plants.
Waterlogging

**Epidemiology.** Pigeonpea is highly susceptible to waterlogging, that can result in the sudden death of plants. Waterlogging is most severe when a few days of rain and cloudy weather are followed by sunny days. Pigeonpea suffers less damage from waterlogging in weedy or intercropped fields, than in well weeded sole cropped fields.

**Symptoms.** Dead plants (Fig. 20) do not show any external stem symptoms and can be easily uprooted. Waterlogged roots are rotten, foul-smelling, and their bark is easy to peel off. It is possible to confuse death due to waterlogging with that due to wilt or phytophthora blight. However, the most characteristic symptom of waterlogging is the presence of brown patches with wavy margins in the collar region, that can be seen when the bark is peeled off (Fig. 21). Reddish-brown discontinuous streaks can be seen in the wood; these differ from wilt streaks which are black and continuous. Death from waterlogging and stem lesions caused by phytophthora blight can sometimes occur simultaneously and in such cases it may be difficult to decide the exact cause of death. In adult plants waterlogging causes sudden death, while phytophthora blight takes time to kill a plant. Adult pigeonpea plants are more susceptible to waterlogging than are seedlings.
Leaf Spots, Blights, and Defoliating Diseases

This Section brings together diseases that affect the foliage. Some of the diseases may cause severe damage, but they rarely lead to death of plants.

Bacterial Leaf Spot and Stem Canker

\textit{Xanthomonas campestris pv. cajani}

(Kulkarni, Patel & Abhyankar) Dye

\textbf{Distribution.} Australia, India, Myanmar (Burma), Panama, Puerto Rico, and Sudan.

\textbf{Epidemiology.} Warm (25-30°C) and humid weather favors disease development. Disease incidence is generally higher in low-lying waterlogged areas of the field than in well-drained areas. African germplasm is more susceptible to the disease than Indian germplasm. Pigeonpeas with purple stems are less susceptible to stem canker than those with green stems. While leaf infection can occur at all stages of plant growth, stem infection usually occurs in younger plants.

\textbf{Symptoms.} In India the disease usually appears in the rainy season during July and August. It can be seen on the lower leaves of plants that are about 1 month old as small necrotic spots surrounded by bright yellow halos. Later, rough, raised, cankerous lesions appear on the stem (Fig. 22). Leaf spots (Fig. 23) do not usually cause defoliation. Cankers can cause stems to break, but the broken part usually remains attached to the plant (Fig. 22). Stems often break at the point where the primary leaves are attached. Often, the affected plants do not break, and the stem cankers increase in size until they are 15-25 cm long (Fig. 24). In cases of severe infection the affected branches dry.
Powdery Mildew

*Oidiopsis taurica* (Lev.) Salmon

(Teleomorph: *Leveillula taurica* [Lev.] Amaud)

**Distribution.** Ethiopia, India, Kenya, Malawi, Sri Lanka, Tanzania, Uganda, and Zambia.

**Epidemiology.** This is a polycyclic disease, i.e., there is an initial infection and secondary spread. Infection is directly proportional to the quantity of inoculum available as conidia. Indian varieties with thin, succulent leaves that are easily colonized by the fungus are more susceptible than those from Kenya that have thicker leaves. The disease develops at temperatures ranging from 20 to 35°C, but 25°C is the optimum. A cool, humid climate is congenial to fungal infection and colonization, but a warm humid climate is good for sporulation and spore dispersal. Sporulation is more frequent on young leaves than on older ones. Plants attacked by sterility mosaic or phyllody support abundant sporulation. Since sterility mosaic and phyllody-infected plants remain green in the field for long periods they provide a continuous source of inoculum. The fungus survives on perennial pigeonpeas and volunteer plants growing in the shade, and on the ratoon growth of harvested stubbles. It also survives as dormant mycelium on infected plant parts, e.g., axillary buds. In India early sowing and irrigation encourage disease establishment.

**Symptoms.** Infected plants have white powdery fungal growths on all their aerial parts, especially the leaves, flowers, and pods (Fig. 25a). Severe infections result in heavy defoliation (Fig. 25b). The disease causes stunting of young plants, followed by the visible symptoms of white powdery growth that appear gradually before the flowering stage. The initial symptoms develop as small chlorotic spots on the upper surface of individual leaves (Fig. 26) and subsequently the corresponding lower surfaces develop white powdery patches (Fig. 27). When the fungus sporulates, this white powdery growth covers the entire lower leaf surface (Fig 28).
Cercospora Leaf Spot

Cercospora cajani Hennings (most prevalent)

Cercospora indica Singh

Cercospora instabilis Rangel

Cercospora thirumalacharii Sharma & Mishra

(Teleomorph: Mycovellosiella cajani [Henn.] Rangel ex Trotter)

Distribution. Bangladesh, Brazil, Colombia, Dominican Republic, Guatemala, India, Jamaica, Kenya, Malawi, Mauritius, Nepal, Nigeria, Puerto Rico, Sri Lanka, Tanzania, Trinidad and Tobago, Uganda, Venezuela, Zambia, and Zimbabwe.

Economic importance. The disease is a problem in humid regions. Yield losses up to 85% have been reported from eastern Africa, and losses are severe when defoliation occurs before flowering and podding.

Epidemiology. Cool temperatures (25°C) and humid weather favor the disease, which normally appears when plants are flowering and podding. Cyclonic rains in southern and north-eastern peninsular India result in sudden outbreaks of the disease in certain years. The disease is more common in the long-duration and perennial pigeonpeas grown in eastern Africa.

Symptoms. First appear as small circular to irregular necrotic spots or lesions usually on older leaves (Fig. 29). These lesions coalesce causing leaf blight and defoliation. During epidemics lesions appear on young branches and cause their tips to dry and die back. The Indian isolates of the pathogen produce a fluffy mycelial growth on their lesions, while the African isolates produce concentric zonations on their lesions (Fig. 30).
Alternaria Blight

*Alternaria* sp

*Alternaria tenuissima* (Kunze ex Persoon)

Wiltshire

*Alternaria alternata* (Fries) Keissler

**Distribution.** India, Kenya, and Puerto Rico.

**Epidemiology.** Not a serious problem in rainy-season crops sown at the normal time, but does cause problems in crops sown late (September), or in the postrainy season on the plains of north-eastern India. Seed infection has only been reported from Puerto Rico.

**Symptoms.** Symptoms develop as small, circular, necrotic spots on leaves (Fig. 31), that develop quickly forming typically concentric rings. The lesions appear on all aerial plant parts including pods. They cause blighting of leaves (Fig. 32), and severe defoliation and drying of infected branches. The fungus sporulates well under warm, humid conditions.
Phyllosticta Leaf Spot

*Phyllosticta cajani* Sydow

**Distribution.** Brazil, India, Jamaica, Puerto Rico, Sri Lanka, and Trinidad and Tobago.

**Epidemiology.** A problem in warm, humid climates; the disease usually appears in July and persists throughout the cropping season. Serious epidemics can develop during October in the north-eastern plains of India. Mean temperatures ranging from 20 to 30°C with a mean humidity range of 73-80% favor severe outbreaks.

**Symptoms.** Round, necrotic spots, up to 10 mm in diameter appear on the leaves. These lesions have wavy dark brown margins with gray centers; they contain characteristically concentric rings of pycnidial bodies (Fig. 33). In severe infections desiccation and defoliation occur.

Fusarium Leaf Blight

*Fusarium semitectum* Berkley & Rav.

**Distribution.** India and Puerto Rico.

**Symptoms.** A problem on pigeonpea crops in the north-eastern hills of India, disease symptoms appear as dark brown, circular to elliptical lesions, 2-10 mm in diameter on the leaves. These lesions originate on leaf margins, and coalesce to form dark brown patches. Infected leaves become yellow and dry prematurely. When the weather is humid, white mycelia with abundant conidia appear on the blighted leaves.
Rust

_Uredo cajani_ Sydow

**Distribution.** Bermuda, Colombia, Guatemala, India, Jamaica, Kenya, Nigeria, Puerto Rico, Sierra Leone, Sri Lanka, Tanzania, Trinidad and Tobago, Uganda, and Venezuela.

**Epidemiology.** Disease severity increases with the onset of flowering. Dense planting and the formation of a closed canopy provide a microclimate favorable for disease development. Light rain, wind, and cloudiness encourage spore release, dispersal, and disease development.

**Symptoms.** Normally seen as dark brown raised pustules full of uredia on the lower leaf surfaces (Fig. 34). The infected leaves desiccate, and drop off. There is extensive defoliation when infections are severe.

Halo Blight

_Pseudomonas syringae pv. phaseolicola_

(Burkholder) Young, Dye & Wilkie

(syn _P. phaseolicola_)

**Distribution.** Australia, Ethiopia, and Zambia

**Symptoms.** The disease develops on leaves as dark-brown angular necrotic spots 1 mm in diameter surrounded by large chlorotic halos 10 mm in diameter. Under humid conditions, these spots coalesce giving the leaves a blighted appearance. The symptoms are more commonly seen on the soft, young leaves of older and ratooned plants. Persistent rains and cloudy weather result in severe disease development.
Botrytis Gray Mold

*Botrytis Cinerea* Persoon ex Fries

**Distribution.** Bangladesh, India, Nepal, and Sri Lanka.

**Symptoms.** Disease symptoms usually appear when plants are flowering, as dark gray fungal growth on the growing tips, flowers, and pods. Infected flowers (Fig. 35) drop, thus reducing pod set. The shed flowers and leaves on the ground are covered with sporulating mycelium of the fungus (Fig. 36).

Marginal Leaf Burning

**Symptoms.** Start with marginal chlorosis and progresses to the "burning" of the margins of leaf laminae (Fig. 37) commonly observed late in the season. The problem is exacerbated by prolonged dry spells. The symptoms first start in lower leaves and progress upwards. They can be distinguished from those of fungal leaf blights by their systematic nature and the absence of chlorotic area between the dried and healthy portions of the laminae that are characteristic of symptoms caused by pathogens.

The reasons for leaf burning are not well understood, but it could be due to soil salinity that results in a gradual accumulation of salts in the leaves.
Mosaics and Sterility

This Section includes some diseases caused by viruses and mycoplasma-like organisms.

Sterility Mosaic

Etiology. Unknown

Vector. Eriophyid mite *Aceria cajani* Channabasavanna

Economic importance. A serious problem in Nepal and India where it is estimated to cause annual pigeon-pea grain losses worth US $ 282 million.

Epidemiology. A single eriophyid mite vector (Fig. 38, x200) is sufficient to transmit the disease. The mites are very small and can be seen easily under a stereoscopic (40x) microscope, they can be wind borne up to 2 km from the source of inoculum. Both pathogen and the mite vector are specific to *Cajanus cajan* and its wild relative *C. scarabaeoides* var. *scarabaeoides* that is commonly found on wastelands and field bunds. Perennial (Fig. 39) and volunteer pigeonpeas, and the ratooned growth of harvested plants provide reservoirs of the mite vector and the pathogen. Disease incidence is high when pigeonpeas are inter- or mixed cropped with sorghum or millets. Symptoms are suppressed during the hot summer months but with monsoon rains they reappear on the new growth. Shade and humidity encourage mite multiplication, especially in hot summer weather.

Symptoms. In the field, the disease can be easily identified from a distance as patches of bushy, pale green plants (Fig. 40) without flowers or pods (Fig. 41). The leaves of these plants are small and show a light and dark green mosaic pattern (Fig. 42). The mosaic symp-
toms initially appear as vein-clearing on young leaves. When infection occurs at 45 days after emergence or later, only some parts of the plant may show disease symptoms, while the remaining parts appear normal (Fig. 43).

Some pigeonpea varieties, e.g., ICP 2376 exhibit ring spot leaf symptoms (green islands surrounded by chlorotic areas), these indicate localized sites of infection of the pathogen (Fig. 44), and such plants produce normal flowers and pods.

Strains of sterility mosaic prevalent in the Indian state of Bihar and in Nepal cause severe internodal shortening of the branches and clustering of leaves. Sometimes these leaves become filiform.

---

**Yellow Mosaic**

**Mung bean yellow mosaic virus**

**Vector.** White fly *Bemisia tabaci* Gennadius

**Distribution.** India, Jamaica, Nepal, Puerto Rico, and Sri Lanka.

**Symptoms.** Affected plants are conspicuous in the field, because of the green and golden yellow mosaic mottle symptoms on their leaves (Fig. 45). Sometimes the affected parts of the leaves become necrotic. Diseased plants are usually scattered in the field, and may produce fewer pods than normal, especially when infected early. Off-season and isolated sowings suffer more from the disease than does the main-season crop, because pigeonpea is not a preferred host of the white fly vectors; they only feed on the crop when forced to by the absence of other host plants.
Witches' Broom

Mycoplasma-like organism

**Vector.** Leaf hopper *Empoasca* sp

**Distribution.** Australia, Bangladesh, Costa Rica, Dominican Republic, El Salvador, Haiti, Jamaica, New Guinea, Panama, Puerto Rico, Taiwan, Trinidad and Tobago, and USA.

**Symptoms.** Infection results in excessive proliferation and clustering of branches with small pale green leaves (Fig. 46). This gives the plant a 'witches' broom' appearance. Such plants rarely produce flowers and pods. Flowers, if produced appear in clusters with elongated pedicels. The whole or part of the plant may exhibit symptoms, depending on the intensity of the disease.

Phyllody

Mycoplasma-like organism

**Vector.** Not known.

**Distribution.** India, Myanmar (Burma), and Thailand.

**Symptoms.** The disease can only be recognised at flowering. Diseased plants are scattered in the field and can be easily recognized because they are bushy with an axillary proliferation of phylloid flowers (Fig. 47). This disease, like yellow mosaic, is seen more often in off-season sowings than in main-season crops, but its incidence is still low. Phyllody differs from witches' broom, as in the former flowers are converted into leafy structures, while in the latter there are no flowers.
Bracteomania

Genetic abnormality

Distribution. India

Symptoms. Affected plants are stunted with few branches, they produce solitary simple leaves with obtuse tips and long petioles attached to their stems, twigs, and floral shoots. Axillary flower buds proliferate into abnormal, clustered inflorescences (Fig. 48). The flowers of affected plants are sessile, small, bunchy, and tightly packed, giving the inflorescences a knotted appearance. Such flowers do not produce normal pods.
Stunting

This Section covers three kinds of nematode-induced diseases commonly characterized by stunting.

Root-knot

*Meloidogyne incognita* (Kofoid & White) Chitwood

*Meloidogyne javanica* (Treub) Chitwood

*Meloidogyne arenaria* (Neal) Chitwood

*Meloidogyne acronea* Coetzee

**Distribution.** Australia, Bangladesh, Brazil, Egypt, India, Kenya, Malawi, Nepal, Puerto Rico, Trinidad and Tobago, Uganda, USA, Zambia, and Zimbabwe.

**Economic importance.** Eight to 35% yield losses have been reported from the Caribbean, Africa, and southeast Asia.

**Epidemiology.** *Meloidogyne incognita* and *M. javanica* are the two most widely distributed root-knot nematode species in tropical, subtropical, and warm temperature climates. They have a very wide host range and occur in an extensive range of soil types, but their association with crop damage is reflective of sandy soils or sandy patches within fields. Weed hosts help to maintain high populations of nematodes in fields. The severity of root-knot disease increases in fields with combined infestations of *M. javanica* and *M. incognita*. Infection by these species increases the severity of fusarium wilt infection.

**Symptoms.** Aerial parts show no characteristic symptoms, but reduced plant vigor (Fig. 49), delayed flowering in a whole or some patches of a field and leaf yellowing are all indicative of nematode infestation. Root galls (knots) are the most characteristic symptom of infection, and can easily be seen with the naked eye (Fig. 50). When the galls are very small, examining roots for the presence of egg sacs is a useful way to confirm nematode infection.
Pearly Root

*Heterodera cajani* Koshy

**Distribution.** Egypt and India.

**Economic importance.** Yield losses as high as 30% have been reported as a result of infection. An initial population density of three juveniles cm$^{-3}$ of soil can cause 25% reduction in plant biomass and yield.

**Epidemiology.** The host range of the cyst nematode *Heterodera cajani* is largely confined to species of the Leguminosae, but *Sesamum indicum* (Pedaliaceae) and *Phyllanthus maderaspatensis* (Euphorbiaceae) are non-legume hosts. *Heterodera cajani* is widespread in sandy loam soils in northern India and in black cotton soils in western and southern India. The nematode lives up to 45 cm deep in soil throughout the year. Summer fallowing reduces densities of *H. cajani* by 45% at 0-15 cm but does not affect densities at lower soil depths. Nematode infestation enhances the aggressiveness of *Fusarium udum* infection in wilt-susceptible pigeonpeas.

**Symptoms.** First noticed as poor and stunted plants evident 30-45 days after sowing (Fig. 51). If the roots of infected plants are carefully examined, many minute, pearl-like, white females of *H. cajani* can be seen attached to them (Fig. 52). These females can be seen with the naked eye, but are more clearly visible through a hand lens (10x). Nematode infestation can delay flowering and pod formation for more than a week.
Dirty Root

Rotylenchulus reniformis Linford & Oliveira

Distribution. Fiji, India, Jamaica, Puerto Rico, and Trinidad and Tobago.

Economic importance. Infestation severely affects pigeonpea production in Fiji, and is associated with variable crop growth in northern India, and on sandy and red soils (Alfisols) in western and southern India. Damage thresholds range from preplant nematode densities of 1.0 to 4.0 cm⁻³ of soil, depending on the soil type and climatic factors.

Epidemiology. This nematode attacks many crops in 38 subtropical and tropical countries. Its extensive host range includes several fruit, vegetable, legume, oil-seed, millet, ornamental, and plantation crops. It can reduce the number of Rhizobium nodules a legume plant produces. Although, the wilt pathogen reduces the density of the nematode, wilt-susceptible genotypes die prematurely when the nematode and the fungus are both present in the soil. The nematode can survive in the absence of a host for more than 300 days without losing its infectivity, but summer fallowing reduces R. reniformis densities to 70% at 0-15 cm soil depth and 36% at 15-30 cm soil depth.

Symptoms. Infected plants generally grow less vigorously than healthy ones (Fig. 53). Infected plants have smaller root systems than healthy plants. If these plants are uprooted egg masses covered with soil are found on their roots (Fig. 54). Infected roots appear dirty because soil particles adhere to the mucilaginous nematode egg sacs, and are not easily dislodged when the roots are shaken. If these roots are dipped in 0.25% trypan blue and rinsed in water, the nematode egg sacs are selectively colored blue while the roots are not stained. This technique can be used to identify reniform nematode infection without using a microscope.
Successful disease management requires integration of such practices as growing resistant or moderately resistant varieties, modification of sowing dates to avoid environmental conditions conducive to disease, use of crop hygiene and cultural practices known to reduce disease severity, and application of appropriate fungicides as soil fumigants, seed protectants, and foliar sprays. Specific packages of practices have to be developed for each crop production system and environment, and socio-economic factors need to be considered. It is therefore not possible to prescribe any overall disease management practice but the information provided in Tables 1-4 should be useful in putting together packages for particular situations.

Key to the Diagnosis of Major Diseases

1. Plants die
   Plants do not die

2. No external restricted lesions on main stem or branches
   Collar rot with white mycelial growth
   Root rot
   Brown chromatographic type lesions on wood at collar region
   External lesions on main stem and branches without enlarged swellings
   External lesions on main stem and branches with enlarged swellings
   Fusarium wilt
   Collar rot
   Dry root rot
   Waterlogging
   See 2
   See 5

3. Lesions elongated, sunken, without discrete margin and galls on their margins
   Lesions localized with discrete marginal acervuli
   Lesions spindle-shaped with gray centers
   Phytophthora blight
   Anthracnose
   Macrophomina stem canker
   Phoma stem canker
   Bacterial stem canker
   See 3
   See 4

4. Enlarged swellings

5. Lesions localized and cankerous
   Plant growth stunted, without any characteristic symptoms on foliage
   Plant growth stunted with characteristic symptoms on foliage
   See 6
   See 7

6. Swelling (knots) on main and lateral roots
   Minute pearl-like white females on roots
   Soil particles adhere to roots, difficult to dislodge by shaking
   Root-knot
   Pearly root
   Dirty root
7. Clusters of closed buds in leaf axils
   White powdery fungal growth on foliar parts
   Dark gray fungal growth on leaves, flowers, and pods
   “Burning” of the margins of leaf laminae
   Necrotic spots on foliage
   Lesions on foliage
   Mosaic, stunting, sterility

8. Necrotic spots circular to irregular
   Necrotic spots small, circular, with pycnidia, and wavy margins
   Necrotic spots large, circular to irregular, with zonation
   Necrotic spots small, with chlorotic halos
   Necrotic spots small, with chlorotic halo

9. Small, dark-brown, raised pustules
   Large necrotic lesions on leaf margins

10. Green and golden mosaic symptoms on leaves
    Light and dark green mosaic symptoms on leaves and sterility
    Small leaves, axillary proliferation, and sterility
    Phyllloid flowers and sterility

Bracteomania
   Powdery mildew
   Botrytis gray mold
   Marginal leaf burning

The semi-arid tropics (SAT) encompasses parts of 48 developing countries including most of India, parts of southeast Asia, a swathe across sub-Saharan Africa, much of southern and eastern Africa, and parts of Latin America. Many of these countries are among the poorest in the world. Approximately one sixth of the world's population lives in the SAT, which is typified by unpredictable weather, limited and erratic rainfall, and nutrient-poor soils.

ICRISAT's mandate crops are sorghum, pearl millet, finger millet, chickpea, pigeonpea, and groundnut; these six crops are vital to life for the ever-increasing populations of the semi-arid tropics. ICRISAT's mission is to conduct research which can lead to enhanced sustainable production of these crops and to improved management of the limited natural resources of the SAT. ICRISAT communicates information on technologies as they are developed through workshops, networks, training, library services, and publishing.

ICRISAT was established in 1972. It is one of 18 nonprofit, research and training centers funded through the Consultative Group on International Agricultural Research (CGIAR). The CGIAR is an informal association of approximately 50 public and private sector donors: it is co-sponsored by the Food and Agriculture Organization of the United Nations (FAO), the World Bank, and the United Nations Development Programme (UNDP).
