SEEDLING ESTABLISHMENT
AND

CROP STANDS IN RABI SORGHUM

(1981-82)

P. Somen Crop Physiologist

SEEDLING ESTABLISHMENT AND CROP STANDS IN RABI SORGHUM (Rabi 1981-82)

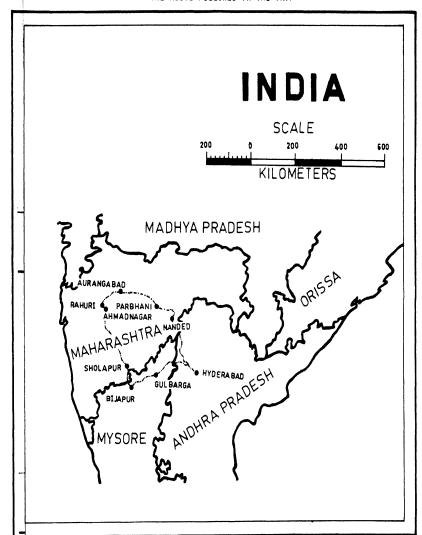

The production of sorghum in many parts of the SAT is thought to be adversely affected by poor crop stands. Some level of quantification of the problem in the farmers fields is found to be necessary at the planning stage of future experimental work on this problem.

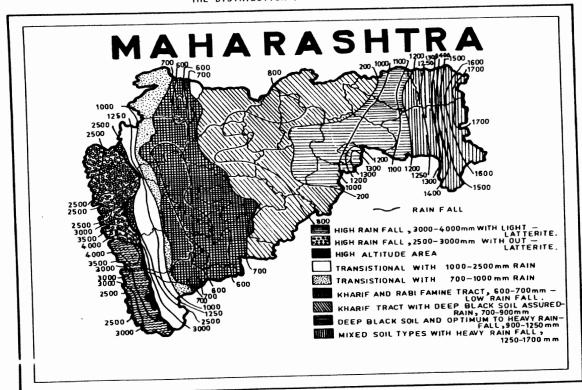

A systematic survey was taken up in a village during the kharif 1981 season (already reported). On a similar line, information on seed and sowing practices and seedling and crop stands were collected from some villages which come within the rabi tract of Maharashtra state and Bijapur district.

Soils in these villages are black with a high water holding capacity. Land preparation and sowing operations are carried out with traditional implements. Sorghum is mostly grown sole or 'intercropped' with safflower or linseed. Fertilizer application was almost nil. Fields were mostly free of weeds at the time of second entry which coincided with the boot stage.

Method of survey

Two sets of observations were made. Information on sowing practice and seed material were collected in early October and later, in December (21-12-81 to 31-12-81), the same fields were visited and stand counts were recorded.

<u>Seed material</u>: Seed samples collected at the time of sowing were brought to the laboratory in polythene bags. Germinability * of these samples were tested in the laboratory.

Observations made at the time of sowing: Information on land preparation, depth of sowing, row width and seeding rate was collected at the time of sowing. Soil samples from the top 2-12 cm were collected for estimating the water content. These samples were brought to the laboratory in cans sealed with a water tight seal. Soil temperatures at the seed zone were also recorded.

Observations on crop stand: Stand counts were taken in December. All plants (damaged and healthy) were counted in 6 m lengths from 5 adjacent rows at 3 random locations in a field. The healthy plants (final stand) were then counted separately. The first count represents the seedling population (% emergence) and the second the potential final stand.

Results

<u>Seed</u>: Type M35-1 (Malthandi) was the most common variety grown in the rabi. It was sown in 74.5% fields. The traditional varieties 5-4-1 Muguthi and Dagadi were also found in Bijapur and Maharashtra respectively. A total absence of hybrids or any other high yielding (HYV) sorghum appear to be a point of special interest.

Source: 95% of the farmers used their own seed kept from the previous year.

Seed treatment: About 48% farmers treated the seeds before sowing. 29% used

sulphur powder and the rest either bullock wrine alone or in combination with

5a.p.....

^{*} Germinability refers to the percent germination

Table : 数许ferent factors related to the seed, environment and management observed in the rabi (Rabi 1981)

FOOT NOTES

- The field for foundation seed was in€luded with a view to observe what goes on when recommendation is followed as against what happens in the real world.
 21 22 23* These fields were at resowing when sampled; very poor seedling stand from the first sowing done in early September, made resowing necessary (Sholapur Mohol).
- 40 41 43* These fields may receive irrigation a month after sowing. These are the only entries which get this exception in this survey (Ahmednagar Rahuri).
- 2* Mixed Sorghum and Safflower
- 81* Mixed Sorghum and Linseed
- or mixed sorghum and tinseed
- 87* Mixed Sorghum and Chickpea
- 88* Mixed Sorghum and Chickpea
 - 7" Pri Xeu 30) gridin and critickp
- 91* Mixed Sorghum and Chickpea
- 92* Mixed Sorghum and Lathyrus
- 96* Mixed Sorghum and Linseed

Unlike the situation in kharif, no seed damage was observed in the rabi.

Germinability: Germination percentages were generally high. Nonetheless, there were cases where the percentage fell below 50. The variability in germination percentage does not seem to be related to the cultivar variety or seed treatment. Once again, these germination percentages do not appear to have influenced the field emergence. In fact, there are instances where field emergence is relatively higher than the germination percentage (Table 2). This situation reiterates the futility of standard germination tests to predict field performance.

Soil types and land preparation: The soils were mostly black and varied much in depth. Many of the shallow soils were also very stoney (chelka) in nature. Only a few fields were ploughed before sowing (23%). A common practice was to use a wooden harrow prior to sowing. Land preparation did not influence emergence ($r^2 = 0.0001$ when regressed on 'plough' and 'no plough' situation). As these implements are light they do not alter the soil profile very much. In many places the previous season's residue had not been removed from the fields. Most of the fields (80%) were kharif fallows.

<u>Sowing</u>: Sowings were done by bullock drawn drills. Only two farmers used seed-cum-fertilizer drill. Depth of sowing varied from 3 to 15 cm. This variability did not depend on the equipment used or the cultivar variety sown. In any case sowing depth does not seem to have influenced percentage emergence ($r^2 = 0.09$).

Physical conditions at sowing: The soil water content (% of dry weight) at the time of sowing ranged from 20 - 40% and seed bed temperature from 25 to 37 °C. The soil moisture and temperature, observed in this rabi promised a good emergence performance. Again, there seemed to be no incidence of soil crusting as there were not any rains to 'seal of' the soil after sowing.

Populations: Seeding rate and seedling population and final stand are given in Tables 1 and 2 respectively.

160,000 plants/ha is the recommended population for rabi (AICRPDA).

However, as shown in Table 1, 56% of the farmers planted to densities well above this figure. 32% planted more than twice the recommended rate. In a rabi environment one might consider populations of the order of 250,000 or more as exceedingly high. However, the plant populations realising more often from such high seeding rates were less than 60% (see Table 2).

As for seedling population, 58% of the fields had above 100,000 and of the rest 60% of the fields had above 70,000. In fact, only two fields had very low populations; field # 47 with 33,000 and field # 58 with 29,000. These findings markedly contrast those observed in the kharif (Aurepalle village study) where only a few fields had seedling populations above 100,000. Seedling emergence in 35% of the fields was above 50% and only 14% showed less than 30% emergence. In kharif, on the contrary, the emergence percentages were very low, often less than 30 (83% of the fields). No specific relation of emergence percentage with cultivar variety was evident. For instance M35-1 the most common cultivar, itself varied from 0% to 98% in emergence performance across fields.

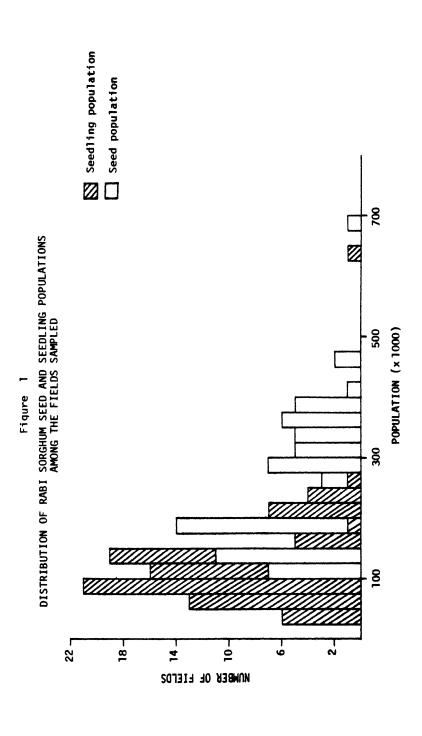

Table 2. Seed, seedling, and final populations (stand) of sorghum in farmers' fields in Bijapur, Sholapur, Ahmednagar, Aurangabad and Parbhani (Rabi 1981-82).

1/ & 2/ The percentages are based upon the seed populations

3/ Rating of the final stand is done as follows:

Less than 20%	Very poor
21 - 40%	Poor
41 - 60%	Good
61 - 80%	Very good
81 - 100%	Excellent

Final stand: The final population was above 100,000 in 31% of the fields.

Of this there was a small fraction (4 fields) with populations above 250,000.

More than 50% of the fields had populations between 50 and 100 thousawd: This amounts to only half that recommended but seems to be a better situation than observed in the kharif.

The change of stand from the seedling stage to harvest is not substantial. This shift was less than 10% in 76% of the fields sampled (Table 2) which might indicate that the pressure from diseases, insects and early season drought are very low. Nevertheless, there were many fields which showed symptoms of a late season drought (These plants are counted in the final stand, as drought symptoms were only starting to set in). A high incidence of striga, 64,000 per hectare were also noted among these fields sampled, though field to field variability was well evident.

Figure 1 shows the distribution of seed and seedling populations among the fields sampled. Compared to the situation in the kharif where these distributions are shifted apart, in the rabi they are intermixed which also shows that the extent of seedling emergence as a problem is less severe in the rabi conditions. However, as in the kharif there exists no significant correlation between the seed and seedling population ($r^2 = 0.12$) i.e., a high seeding rate does not guarantee high seedling emergence. The emergence percentage when regressed on % germination, % soil water content (w/w), seed bed temperature (0 C) and sowing depth did not show any significant correlation ($r^2 = 0.04$). Table 3 shows the regression coefficients and their test of significance. It appears that these factors could not explain the variability in emergence. This situation provided a parallel with what was found from the kharif survey.

Table 3. The regression coefficients from a multiple regression of emergence percentage for sorghum on % germinability, % soil water content (w/w), seed bed temperature $^{\rm O}{\rm C}$ and sowing depth (cm)

Independent variables	Regression coefficient	t test for the regression co- efficients
% germinability	0.23	1.93 ^{NS}
% water content of soil	-0.19	0.64 ^{NS}
Seed bed temperature	-0.43	0.45 ^{NS}
Sowing depth	-0.41	0.39 ^{NS}

NS = Not significant

Conclusion

In the rabi the problem of seedling establishment does not seem to be as severe as in the kharif. In both situations, however, the extent of emergence did not relate to the factors related to seed, environment and management.
