PROGRESS REPORT 3 OF
PROJECT NO: 8-106(B3)IC
GROUNDNUT PHYSIOLOGY

Screening of groundnut genotypes for drought tolerance

Post-rainy season
1987/88

R.C.N. Rao and J.H. Williams

This is not a formal publication and should not be quoted.
It has been prepared and made available for use by persons
interested in drought responses of groundnut genotypes. The
authors welcome comments, criticism and suggestions.

During 1987-1988 postrainy season we screened 144 groundnut genotypes for tolerance to drought in the field. Among these, 124 genotypes belonged to var festucata and vulgaris of sub species festucata (Spanish and valencia types) (Expt. A) and the rest 20, belonged to var hypogaea of subspecies hypogaea, (Virginia bunch types) (Expt.B).

Among 124 spanish and valencia lines 58 genotypes were breeding lines and the rest 66 were germplasm accessions. Among 24 virginia bunches, 13 were breeding lines, and 7 were progenies derived from wild species.

Land preparation and crop management

This experiment was conducted at the ICRISAT center during 1986-87 post-rainy season on an alfisol. The field (RP 2A) was disc ploughed and a basal dose of Diammonium phosphate (18N : 46 P₂O₅) at the rate of 100 kg ha⁻² was incorporated into the soil at the time of land preparation. The field was harrowed and prepared into broad beds of 1.2 m width with 0.3 m wide furrows between beds.

Before sowing, seeds were treated with Thiram and Captan each at the rate of 3 g kg⁻¹ seed to prevent seedling diseases. The entries were sown in paired rows of 12 m length each with a

spacing of 30 cm between rows and 10 cm between plants within a row. Thus each plot of 12 m length consisted of 8 beds perpendicular to the sprinkler line.

The crop was regularly irrigated at 10-day intervals until 40 days after sowing to favour crop establishment, after which the treatments were introduced. Plant protection against pests and diseases was provided as and when required and the crop was maintained weed-free throughout the season. Days to first flower appearance and 50% flowering (50% of plants to flower) were recorded (Table 1a & b). Appearance of first flower occurred between 37 to 44 DAS in Expt 'A' and 38 to 49 DAS in Expt 'B' while 50% occurred between 42 to 57 DAS in Expt 'A' and 45 to 53 DAS in Expt 'B'.

Statistical design and Treatments

The genotypes in Expt 'A' and 'B' were sown in two separate blocks due to their differences in duration, hence considered as two different experiments. Genotypes within each block were randomized as RBD.

There were two drought treatments, which were different in timing and duration of drought imposed.

These two treatments were replicated three times. The schedule of the timing and duration of droughts in the 3 treatments was as follows:

<u>Expt. A</u> (bunch types)	Treatment period	Duration(Days)
	Days after sowing	
T1	40 - 129	89
T2	93 - 129	36

Expt. B (Virginia bunch genotypes)

T1	40-130	90
T2	93-130	37

Drought intensities

Eight levels of irrigation (intensities) were applied during the period of each treatment using a line source sprinkler system (Hanks et al., 1976).

The sprinkler head had dual nozzles of 1/8" and 5/32" aperture size and had an output of about 40 l min^{-1} when operated at 1.3 Mpa. The line source sprinkler system was operated during periods when the wind velocity was minimal (less than 3 km hr^{-1}), usually at nights.

The water applied during each irrigation was measured by placing catchcans perpendicular to the sprinkler line in each of the 8 beds at 3 different locations in each replication. The volume of water collected in each of the catchcans was measured and averaged over 3 locations to estimate the water applied to each bed in a given replication. The amount of water applied for each bed is accumulated over the effective duration of the treatment.

The cumulative amount of water applied along with the mean meteorological data during the period of treatments are presented in Table 2.

Harvesting

Bunch genotypes were harvested on 20th April 1988 (129 DAS) by which time about 70% of pods in the non-stress plots (Bed 1) had matured, while Virginia types were harvested on 22nd April 1988 (131 DAS). Pods of several virginia types were still immature by that time, but the experiment was harvested to accommodate closed season policy at this site.

Yield measurements

The bulk vegetative weights of each genotype across 8 beds were weighed in the field and dry weights of these were calculated using the oven dry/fresh weight ratios of representative samples taken at a rate of 1:8. The air-dried pod weights were recorded for each genotype separately in each bed.

Statistical analysis

The drought intensities within each treatment are expressed as % water deficit which was calculated using the formula:

$$\% \text{ Water deficit} = \frac{x_1 - x_2}{x_1} \times 100$$

where

x_1 = Cumulative pan (class "A") evaporation which occurred only during the period of treatment.

x_2 = Cumulative amount of water applied for the period of treatment.

In this analysis the response of genotypes to variation in applied water was obtained by regressing total biomass m^{-2} and total pod weight g^{-2} with the variable water deficit in the respective plots. Since the water applied at a given intensity varied in 3 replications within a treatment, the regression analysis was done treating replicate values as individual data points. Thus, regression analysis for each genotype contained 24 (8 intensities \times 3 replications) data values. In this report the regression coefficients for total biomass and total pod weight for each genotype are presented in Tables 3 to 10. The mean of the regression coefficients of all entries in each experiment

are presented at the bottom of every page for easy comparison. The mean regression equations were derived by regressing the mean of all the entries within each water level against the respective percent water deficit.

Comments relating to tolerance or susceptibility of a genotype to drought have been based on the performance of the genotype across all drought intensities relative to the regression derived from the mean of the group in each replication. Each genotype is rated as 'S' (susceptible), 'T' (Tolerant) or '-' not different from mean response, considering its performance in individual replication. If a genotype is superior to the mean response (across all water deficits) in all the three replications, then it is rated as 'T'. Comments confined to one or two replicates may be modified in future based on positional effects using the systematic check variety and/or the lattice design.

Genotypes with above average performance in all the three replications in the specified drought treatments are listed in the Table 11.

production studies. Soil sci. soc. Am. Proc. 40: 426-429.

INDEX FOR TABLES

- * = When F ratio of the Regression is not significant, mean and SE of mean of the cultivar across 8 levels of water stress (3 replications) is provided.
- T/S levels = Lines selected for either drought tolerance (T) or susceptibility (S) based on total biomass or total pod productivity in 8 of water stress in all replications.
- 2T or 2S = Tolerant or susceptible in two replicates only.
- % VAR = The difference between residual and total mean squares expressed as a percentage of the total mean square.
