ABSTRACT

Proso millet is an important short-duration crop that adapts well to varied climatic conditions and is grown worldwide for food, feed and fodder purposes. Owing to a lack of genetic improvement, the crop has experienced no yield improvement and provides low income to farmers. In this study, 200 accessions of proso millet originating in 30 countries were evaluated in two rainy seasons to assess phenotypic diversity for morpho-agronomic and grain nutritional traits and to identify high grain-yielding and grain nutrient-rich accessions. Proso millet diversity was structured by geographical region, by country within region, and by racial group. Race *patentissimum* showed high diversity and *ovatum* low diversity, and diverged widely from each other. The lowest divergence was observed between races *compactum* and *ovatum*. Eighteen high grain-yielding, 10 large-seeded, and 26 two or more grain nutrients-rich accessions were identified, and highly diverse pairs of accessions within and between trait groups were identified. They included IPm 9 and IPm 2661 for high grain yield and large seed size; and IPm 2069, IPm 2076, and IPm 2537 for high Fe, Zn, Ca, and protein contents. IPm 2875 had a seed coat that is readily removed by threshing. This study provides valuable information to proso millet researchers about agronomic and nutritional traits in accessions that could be tested for regional adaption and yield for direct release as cultivars, and could be used in breeding for developing high grain-yielding and nutrient-rich cultivars.

1. Introduction

Small millets, including finger millet (*Eleusine coracana* (L.) Gaertn.), foxtail millet (*Setaria italica* (L.) P. Beauv.), proso millet (*Panicum miliaceum* L.), kodo millet (*Paspalum scrobiculatum* L.), little millet (*Panicum sumatrense* Roth. ex. Roem. & Schult.), and barnyard millet (*Echinochloa crus-galli* (L.) P. Beauv. and *E. colona* (L.) Link) are well adapted to diverse climatic conditions and play an important role in food and nutritional security in rural

households in regions where these crops are grown. Proso millet is one of the important small millets, commonly known as broomcorn millet, common millet, hog millet, Russian millet, and by other names in different regions. Vavilov [1] suggested China as the center of diversity of proso millet, while Harlan [2] suggested that proso millet was probably domesticated in China and Europe. Proso millet grows at a wide range of altitudes, with a short growth cycle of 6 to 12 weeks, and requires little water for growth and development. It is grown in northern China, Mongolia, Republic of Korea, southeastern Russia, Afghanistan, Pakistan, India, and southern Europe. The cultivation area of proso millet is 0.82 m ha in Russia, 0.7 to 1.0 m ha in China [3], 0.5 m ha in India [4] and 0.20 m ha in USA [5]; however, the area in proso millet cultivation is declining owing to a shift to cultivation of major crops that give much higher yields and profit.

Proso millet is used for feeding birds and as livestock feed in developed countries and for food in some parts of Asia [6]. In the USA, most of the proso millet crop is used for birdfeed and in cattle-fattening rations [5]. Nutritionally, proso millet grains are rich in protein, vitamins, minerals, and micronutrients including iron, zinc, copper and manganese, compared to other staple cereals [7]. The protein content of proso millet (12.5%) is comparable with that of wheat and its grains are richer in essential amino acids (leucine, isoleucine, and methionine) than those of wheat [8, 9]. The husked grain is nutritious and is eaten whole, boiled, or cooked like rice (*Oryza sativa* L.). Sometimes it is ground to make roti (flatbread). Starch is the main carbohydrate in the grain and is similar to corn starch; it is suitable as a sizing agent in the textile industry. Green plants are excellent fodder for cattle and horses and are also used as hay. Proso millet can be a substrate for distilled liquors and beers and is used to make fermented beverages in Africa and Asia. Proso millet has been receiving growing interest from food industries in Europe and North America because of its mild flavor, light color, gluten-free quality, and potential health benefits [3].

Grain yield enhancement is one of the main objectives of proso millet breeding programs; however, limited crop-improvement research efforts and production and processing technologies result in low yields and farmer profit. Cultivars of proso millet have been developed mostly by selection from landraces and a few by hybridization followed by selection (<http://www.aicrpsm.res.in/Releasevarieties.html>) [5]. Globally, over 29,000 germplasm accessions of proso millets have been conserved in genebanks, with the major collections of proso millet germplasm accessions held in Russia, China, Ukraine, and India [10]. In the ICRISAT genebank, 849 accessions of proso millet are held, and a core collection (106 accessions) representing the entire collection has been established [11]. Assessment of proso millet germplasm diversity for various morpho-agronomic and grain quality traits and their use in crop improvement programs would help in breeding high-yielding cultivars, would contribute to crop and diet diversification, and would reduce micronutrient and protein malnutrition. No comprehensive study of yield and grain nutritional trait diversity in proso millet is available. The present study was initiated to assess the phenotypic diversity of the global proso millet germplasm collection for morpho-agronomic and grain nutritional traits, to assess association of grain yield and

contributing traits with grain nutritional traits, and to identify high grain-yielding and grain nutrient-rich accessions for use in proso millet improvement.

2. Materials and methods

2.1. Experimental details

A total of 200 accessions including 106 from a core collection [11] originating in 30 countries, representing five races of proso millet (60.5% *miliaceum*, 12.5% *compactum*, 12.0% *contractum*, 8.5% *patentissimum*, and 6.5% *ovatum*), were included in this study. These accessions were selected using the cluster information of proso millet which was used to assemble core collection [11]. This set represents 24% of the entire collection and 22% to 27% of each race of proso millet germplasm conserved at the ICRISAT genebank. These accessions were evaluated for morpho-agronomic traits during the 2015 and 2016 rainy seasons at ICRISAT, Patancheru, Telangana, India (17°51'N, 78°27'E, 545 m a.s.l.). Accessions were planted in the third week of July in both years, in an alpha design with two replications. The experiments were planted on red soils (Alfisols) and seed was sown on ridges 60 cm apart. Each accession occupied a single row of 4 m length, with a plant-to-plant spacing of 10 cm. Diammonium phosphate was applied at the rate of 100 kg ha⁻¹ as a basal dose to supply nitrogen and phosphorus. In addition, 100 kg ha⁻¹ of urea was applied as top dressing. The precision fields at the ICRISAT center have uniform fertility and a gentle slope of 0.5%. Irrigation and hand weeding were applied as needed.

2.2. Data collection

Observations for eight qualitative and 14 agronomic traits were recorded following the descriptors of *P. miliaceum* [12]. Data for all qualitative traits (growth habit, culm branching, sheath pubescence, ligule pubescence, leaf pubescence, inflorescence shape, seed color, and apiculus color), and three agronomic traits namely days to 50% flowering, days to maturity, and grain yield were recorded on a plot basis. The agronomic traits namely plant height, basal tiller number, flag leaf blade length, flag leaf blade width, flag leaf sheath length, peduncle length, panicle exertion, inflorescence length, number of nodes per main stem, and inflorescence primary branch number were recorded on the main culms of five representative plants in a plot. Bulk seeds of each accession were used to determine 100-seed weight. The measure of grain yield per plot was converted into grain yield kg ha⁻¹.

For grain nutritional content estimation, accessions were harvested at maturity and care was taken to avoid contamination of grains with dust and metal particles during their cleaning. A random well cleaned grain sample (unhusked) from each accession was used to estimate grain protein, calcium (Ca), iron (Fe), and zinc (Zn) contents at the Charles Renard Analytical Laboratory, ICRISAT. Grain Ca, Fe, and Zn contents were assessed by nitric acid and hydrogen peroxide digestion followed by inductively coupled plasma optical emission spectrometry [13]. Protein content in grain samples

was determined by sulfuric acid–selenium digestion followed by total nitrogen (N) estimation in a SKALAR SAN⁺⁺ SYSTEM autoanalyzer and protein % calculation as $N\% \times 6.25$ conversion factor [14].

2.3. Statistical analysis and trait-specific source identification

The 14 agronomic and four grain nutritional traits were analyzed separately for each rainy season and pooled over the two rainy seasons using residual maximum likelihood (REML) [15] in GenStat 17 (<https://www.vsni.co.uk/>) considering genotypes as random and season as fixed. The significance of season was tested using Wald's statistic [16]. Variance components due to genotype (σ^2_g) and genotype \times season (σ^2_{gs}) and their standard errors (SE) were estimated.

Best linear unbiased predictors (BLUPs) [17] were obtained for agronomic and grain nutritional traits for each accession for individual seasons as well as pooled over the two seasons. On the basis of BLUPs derived from the pooled seasons, the range, mean and variances were estimated. Mean performances of races for the agronomic and grain nutrient traits were compared using the Newman-Keuls test [18, 19] and the homogeneity of variances among races were tested using Levene's [20] procedure using the R packages *agricolae* [21] and *car* [22], respectively. Broad-sense heritability (h^2_b) was estimated for individual seasons and combined over the two seasons for each trait, to estimate the fraction of the total variation among individuals that is attributable to genetic variation, and categorized as low (<0.30), moderate (0.30 to 0.60), or high (>0.60). Principal component analysis (PCA) was performed to estimate the relative importance of different traits in capturing the variation. Genetic correlations were estimated to determine trait associations at the genetic level using META-R 6.0 [23]. The Shannon–Weaver diversity index H' [24] was used as a measure of the phenotypic diversity of eight qualitative, 14 agronomic, and four grain nutritional traits using GenStat 17 (<https://www.vsni.co.uk/>). Gower's [25] dissimilarity matrix was constructed using morpho-agronomic and grain nutritional traits using the R package *cluster* [26], and accessions were clustered by neighbor joining [27] using the software DARwin 6.0.14 [28]. On the basis of proso millet accessions grown in two rainy seasons, accessions with high grain yield, large seeds, and high grain Fe, Zn, Ca, and protein were identified, and Gower's distance matrix was used to identify the most diverse pairs of accessions for potential use in proso millet improvement.

3. Results

3.1. Variance components and heritability

The REML analysis showed that variances due to genotype (σ^2_g) were significant for all 14 agronomic and four grain nutritional traits in the individual rainy seasons and pooled over the two seasons, indicating the presence of high levels of variation in the proso millet germplasm accessions (Table 1). Except for basal tiller number, panicle exertion, and protein content, all traits showed significant genotype \times season interaction (σ^2_{gs}) indicating that accession interacted with

season. Wald's statistics for season was significant for all traits except peduncle length, indicating the significant influence of the season on expression of these traits. The estimates of h^2_b indicated high heritability of all the traits in individual years (0.75 for basal tiller number to 0.98 for inflorescence length in 2015; 0.60 for 100-seed weight to 0.97 for inflorescence length and grain yield in 2016) (Table 1). In the combined analysis over both seasons, basal tiller number (0.37) and Fe content (0.51) showed moderate heritability, whereas the remaining traits showed high heritability.

3.2. Proso millet diversity and structure

3.2.1. Qualitative traits

The frequency distributions of different phenotypic classes of the eight qualitative traits showed large variation (Table S1). In the full set, decumbent growth habit (68.0%), high culm branching (49.5%), medium sheath pubescence (41.5%), sparse and medium ligule pubescence (43.0% and 41.5%, respectively), sparse leaf pubescence (52.0%), diffuse sparse and diffuse dense inflorescence shape (29.5% and 23.0%, respectively), light brown-colored seed (37.0%), and straw apiculus color (62.5%) were the predominant classes. However, frequencies of qualitative traits varied among races. The majority of accessions in *compactum* (84.0%), *contractum* (54.2%), *miliaceum* (71.1%), and *ovatum* (77.0%) had decumbent growth habit, whereas the accessions of race *patentissimum* had erect growth habit (52.9%). High culm branching in *compactum* (60.0%) and *miliaceum* (55.4%) and medium culm branching in *ovatum* (61.5%) were the most prevalent, whereas accessions of race *contractum* and *patentissimum* had all three classes of culm branching (high, medium and low) at 29.0% to 38.0%. The majority of *contractum* (50.0%), *miliaceum* (43.8%), and *ovatum* (53.8%) accessions had medium sheath pubescence, whereas *compactum* and *patentissimum* accessions had sparse (44.0%) and dense (41.2%) sheath pubescence, respectively. All races had sparse leaf and ligule pubescence in higher frequency except *miliaceum*, which had medium ligule pubescence in higher frequency. For inflorescence shape, arched dense inflorescence in *contractum* (70.8%), elliptic dense (48.0%) and elliptic sparse (40.0%) inflorescence in *compactum*, diffuse sparse (46.3%) and diffuse dense (36.4%) inflorescence in *miliaceum*, globose dense (61.5%) and globose sparse (30.8%) inflorescence in *ovatum* and arched sparse (70.6%) inflorescence in *patentissimum* were in high proportion. Light brown seed was in higher proportion among accessions of each race, followed by straw and white colored seed, and the majority of accessions in each race and in the full set had straw apiculus color (Table S1). The H' revealed that in the full set, seed color had the highest diversity (0.72) followed by inflorescence shape (0.50) and apiculus color the lowest (0.29) (Table 2). Seed color had the highest H' (0.59 to 0.71) in all races, and growth habit in *compactum* (0.23) and inflorescence shape and apiculus color in all five races had the lowest H' . A low H' of inflorescence shape within each race is because accessions were classified into races based on inflorescence shape [29]. The mean H' was 0.46 in the full set ($n = 200$), and the race *miliaceum* (0.42) had the highest H' among races.

Table 1 – Variance components due to genotype (σ_g^2) and genotype \times season interaction (σ_{gs}^2), and broad-sense heritability (h_b^2) for agronomic and grain nutritional traits of proso millet accessions evaluated in two rainy seasons at ICRISAT, Patancheru, India.

* Significant at $P \leq 0.05$.
** Significant at $P \leq 0.01$.

3.2.2. Agronomic traits

A wide range of variation was observed for agronomic traits, in the full set as well as within each race (Table 3). Days to 50% flowering varied from 19 to 47 days after sowing (DAS), basal tiller number from 1.9 to 4.9, flag leaf blade width from 11 to 24 mm, peduncle length from 99 to 287 mm, panicle exertion from 15 to 199 mm, number of nodes per main stem from 2 to 6, and days to maturity from 49 to 79 DAS; and none of these traits showed a significant difference among races. Plant height, flag leaf blade length, flag leaf sheath length, inflorescence length, inflorescence primary branch number, 100-seed weight, and grain yield varied among races. Accessions of *patentissimum*, *miliaceum*, and *contractum* were tall (average 73–78 cm) and produced long panicles (average 213–234 mm), and differed significantly from *compactum* and *ovatum* (averaging 48–58 cm plant height and 108–160 mm inflorescence length). Flag leaf blade length varied from 95 to 370 mm, flag leaf sheath length from 54 to 127 mm, and inflorescence primary branch number from 9 to 20, and these traits did not differ significantly among *compactum*, *contractum*, *miliaceum* and *patentissimum*, whereas all four races differed significantly from race *ovatum*, which had short flag leaf blade length (average 161 mm) and flag leaf sheath length (average 72 mm) and low inflorescence primary branch number (average 12) and 100-seed weight (average 0.47 g). Grain yield varied from 15 to 2334 kg ha⁻¹, with a mean of 736 kg ha⁻¹. Among races, accessions of *patentissimum*, *miliaceum* and *contractum* produced highest average yield (746 to 880 kg ha⁻¹) and differed significantly from race *ovatum*, which produced lowest grain yields (average 286 kg ha⁻¹). The variances were heterogeneous for days to 50% flowering, plant height, flag leaf blade length, flag leaf blade width, flag leaf sheath length,

inflorescence length, number of nodes per main stem, days to maturity and grain yield among races (Table 3). The H' for the 14 agronomic traits indicated that panicle exertion had high H' in races *contractum* (0.59), *ovatum* (0.55), and *patentissimum* (0.57), whereas *compactum* had the highest H' value for inflorescence primary branch number (0.60) and *miliaceum* for flag leaf blade width (0.62) and 100-seed weight (0.62) (Table 2). Among races, *miliaceum* had the highest H' (0.57).

3.2.3. Grain nutritional traits

Proso millet accessions showed a wide range of variation for grain nutrient content: Fe, 41–73 mg kg⁻¹; Zn, 26–47 mg kg⁻¹; Ca, 91–241 mg kg⁻¹; protein, 11%–19%. Mean grain nutritional contents were Fe, 54 mg kg⁻¹; Zn, 36 mg kg⁻¹; Ca, 165 mg kg⁻¹; and protein, 14%. Accessions of *ovatum* had highest grain nutrients: Fe, 60 mg kg⁻¹; Zn, 40 mg kg⁻¹; Ca, 193 mg kg⁻¹; and protein, 16%, and differed significantly from *contractum*, *miliaceum*, and *patentissimum*, whereas *compactum* had comparable grain nutrients and did not differ significantly from *ovatum* with respect to Fe and Ca contents. The variances were homogeneous among races for Fe, Zn, and Ca contents and heterogeneous for protein content (Table 3). Grain nutritional traits had high H' ranging from 0.62 (for Fe, Zn, and Ca contents) to 0.64 (protein %) in the full set, and race *miliaceum* had high H' (0.61).

3.2.4. Phenotypic distance and racial structure

Gower's phenotypic distance matrix among 200 accessions based on 26 traits (eight qualitative traits, 14 agronomic traits and four grain nutritional traits) was estimated. The average distance was 0.270 among 19,900 pairs of accessions ($n = 200$), and varied from 0.037 (between IPm 390 and IPm 361, both belonging to race *miliaceum* and originating in India) to 0.618

Table 2 – Shannon-Weaver diversity indices (H') of qualitative, agronomic and grain nutritional traits in a full set ($n = 200$) and five races of proso millet evaluated in two rainy seasons (2015 and 2016) at ICRISAT, Patancheru, India.

(between IPm 2577 and IPm 381, both belonging to race *miliaceum*, and originating in Russia and India, respectively). Among races, *patentissimum* had highest average distance (0.309, with range 0.100–0.551), followed by *contractum* (0.262, range 0.072–0.511), *miliaceum* (0.258, range 0.037–0.618), and *compactum* (0.228, range 0.049–0.448), whereas *ovatum* had the lowest diversity (average distance 0.187, range 0.082–0.368) (data not shown). The average distance between accessions of *patentissimum* and *ovatum* was high (0.324), whereas the lowest divergence was between races *compactum* and *ovatum* (0.233) (Table S2). An unweighted neighbor joining tree based on Gower's phenotypic distance grouped accessions into two major clusters (C1 and CII) (Fig. 1). Accessions were clustered largely according to geographical region and country within region (Fig. 1-A) and racial group (Fig. 1-B). Accessions originating in Asia were largely in C1, while those from Europe and the Americas were in CII, and accessions from Russia, India, Mexico, Republic of Korea and Syria were distinctly clustered (Fig. 1-A). Accessions of *miliaceum*, *contractum*, and *patentissimum* were distributed in both clusters, whereas accessions of *compactum* and *ovatum* were in CII (Fig. 1-B).

3.2.5. PCA and trait association

PCA revealed the importance of the first three PCs, which explained about 76% of total variance among agronomic and

grain nutritional traits (data not shown). Days to 50% flowering, plant height, flag leaf blade length, flag leaf sheath length, inflorescence length, number of nodes per main stem, days to maturity, grain yield, and protein content contributed largely to PC1, which explained about 52% of total variance. Genetic correlation coefficients among 14 agronomic and four grain nutritional traits indicated that all of the agronomic traits were positively and significantly correlated with grain yield except panicle exertion and peduncle length, both showing significant negative correlations with grain yield (Table 4). All four grain nutrient traits showed significantly negative correlations with grain yield; however, all of them were positively correlated with one another and also with panicle exertion and peduncle length, except for peduncle length with Fe.

3.3. Trait-specific sources and their agronomic performance

3.3.1. Agronomic traits

Grain yield and 100-seed weight are the important agronomic traits of focus in proso millet improvement. Grain yield of proso millet accessions varied from 15 to 2334 kg ha^{-1} , with a mean of 736 kg ha^{-1} . Accessions that produced grain yields $>1500 \text{ kg ha}^{-1}$ were considered as high grain-yielding, so that 18 accessions with grain yield ranging from 1601 to

Table 3 – Range, mean, and variance of agronomic and grain nutritional traits in proso millet germplasm evaluated in two rainy seasons (2015 and 2016) at ICRISAT, Patancheru, India.

2334 kg ha⁻¹ were selected (Table 5). Days to 50% flowering of these high-yielding accessions varied from 33 to 42 DAS and they matured in 65 to 75 DAS. High grain-yielding accessions belonged largely to *miliaceum* (13 accessions), followed by *patentissimum* (3 accessions) and *contractum* (2 accessions), originating mostly in India (11 accessions), with two accessions from Sri Lanka and one each from Pakistan and Nepal. For large-seeded accessions, 10 accessions (100-seed weight ranging from 0.60 to 0.66 g), significantly larger than the trial mean of 0.50 g were identified. Two high-yielding accessions (IPm 2661 and IPm 9) also had significantly large seeds and produced grain yields of 1601 and 2334 kg ha⁻¹, respectively. Altogether, 26 accessions (16 high grain-yielding accessions, eight large-seeded accessions, and two high grain-yielding and large-seeded accessions) were identified.

3.3.2. Grain nutritional traits

Assessment of grain nutritional content of proso millet accessions resulted in identification of grain nutrient-rich accessions with contents significantly higher than the trial mean. These included 12 accessions for Fe (63.3–73.2 mg kg⁻¹), 27 accessions for Zn (40.6–46.7 mg kg⁻¹), 56 accessions for Ca (185.5–241.2 mg kg⁻¹), and 27 accessions for protein (16.1%–19.1%) (Table S3). All of the selected accessions had significantly higher grain nutrient content than the best high grain-yielding accession, IPm 9. The search for accessions with two or more grain nutrients among these nutrient-rich accessions resulted in identification of 28 accessions (Table 6). Days to 50% flowering of the accessions with multiple grain nutrients varied from 19 to 29 DAS and they matured in 49 to 61 DAS. However, grain yields of these accessions were low (average 233; range 15–917 kg ha⁻¹). These accessions belonged mostly to race *miliaceum* (11 accessions) followed by *ovatum* (6 accessions), *compactum* (5 accessions), *patentissimum* (4 accessions), and *contractum* (2 accessions), and most originated in Russia (8 accessions) (Table 6), whereas 11 accessions were of

unknown origin and one accession each was from Afghanistan, China, Hungary, Republic of Korea, Syria, Turkey, the United Kingdom, Ukraine, and Kyrgyzstan.

3.3.3. Genetic distances among trait-specific sources

Phenotypic distances between pairs of accessions within the sources for agronomic traits (high yield and large seed size) and accessions rich in multiple grain nutrients, and between accessions with agronomic traits and those with multiple nutrients were estimated. Average distance was 0.279 among agronomically superior accessions, 0.213 among multiple grain nutrient-rich accessions, and 0.383 between accessions with agronomic traits and multiple grain nutrients. The 10 most diverse pairs of accessions were identified within each trait group (high grain yield, multiple grain nutrients) and between high grain-yielding and multiple-nutrient accessions (Table S4).

4. Discussion

Small millets' presence in the food basket has been declining over the years, mainly because of the increased availability of rice and wheat (*Triticum aestivum* L.) and other staple foods, a lack of crop improvement efforts in developing high yielding cultivars, and a lack of modern technologies for processing and utilization [10]. Over the last few years, there has been increasing recognition of small millets' nutrient composition and benefits as healthy food. Considering their diverse adaption and agronomic and health benefits, small millets could be an alternate or supplementary crop to enlarge the food basket to ensure food, feed, and nutritional security. Proso millet is one of the under-researched and underutilized small millets, and a potential climate-smart and nutrient-rich crop. With its short growing season, proso millet can be planted late as a catch crop when main crops fail [3].

Table 5 – Proso millet germplasm accessions identified as high grain-yielding and large seeds and their agronomic performance based on evaluation in two rainy seasons (2015 and 2016) at ICRISAT, Patancheru, India.

Knowledge of diversity and structure of germplasm resources is important for their use in crop improvement programs. The characteristics and diversity of proso millet accessions and races were assessed using morpho-agronomic and grain nutritional traits revealed a wide range of variation. Overall, accessions of *ovatum* were low grain-yielding, and characterized by short plants with short flag leaf blade length, flag leaf blade sheath length, and inflorescence length, and medium culm branching and sheath pubescence, compared to other races, and had globose dense or globose sparse inflorescence. Accessions of *compactum* were slightly high yielding, tall and with long panicles compared to *ovatum*, while flag leaf blade length, flag leaf sheath length and inflorescence primary branch numbers were higher than in race *ovatum* and did not show significant difference from other races, and produced high culm branches and elliptic dense and elliptic sparse inflorescences. Accessions of *contractum*, *miliaceum* and *patentissimum* did not show significant difference for the agronomic traits studied, however average grain yield of *patentissimum* was higher than that of other races. The majority of *patentissimum* accessions produced dense sheath pubescence and arched sparse inflorescence, while *contractum* had medium sheath pubescence and arched dense inflorescence and *miliaceum* had medium sheath pubescence and diffuse dense and diffuse sparse inflorescence.

Among the races, *miliaceum* had the highest H' for all the traits studied including qualitative, agronomic and grain nutritional traits, and all the five races had comparatively rich diversity. Estimation of pairwise distance between accessions based on 26 traits including eight qualitative, 14 agronomic, and four grain nutritional traits revealed that the average distance of accessions within race *patentissimum* was high (0.309), whereas *ovatum* had the lowest distance (0.182), and these races diverged widely from each other. The lowest divergence was observed between races *compactum* and *ovatum*. Population structure as revealed by neighbor-joining clustering indicated that the accessions of proso millet were structured largely according to geographical region, country within region, and racial group. Accessions originating in Asia and Europe were distinctly grouped, accessions from Asia showed high diversity (average distance 0.268) relative to those from Europe (average distance 0.225), and high diversity was observed between accessions of Asia and Europe (average distance 0.301). This finding supports independent origins of proso millet in Europe and Asia, or may correspond to a domestication within Asia followed by a spread westward across the Eurasian steppe [30]. Accessions of *miliaceum*, *contractum*, and *patentissimum* were distributed in both clusters, whereas accessions of *compactum* and *ovatum* were present in the same cluster, supporting the observation that these two races were less diverged from each other than with other races. Rajput and Santra [31] assessed genetic diversity and structure of 90 proso millet accessions and reported that they were structured partially according to geographical origin.

Among the millet species produced worldwide, proso millet is the most important species traded in the world market, and the USA is among the top producers [5]. The USA generally exports 15–20% of its annual millet production to over 70 countries, primarily as feed, and the largest export markets for USA proso millet include the Netherlands, the

United Kingdom, Canada, and Japan [5]. The current marker for proso millet is limited mostly to bird feed, but there are many other uses including for human food and alcoholic beverages, livestock and poultry feed, and biofuel ethanol [32]. Genetic improvement and cultivar development of proso millet, as in other small millets, has been achieved largely through direct selection of promising germplasm. In the USA, of 15 cultivars of proso millet available to growers, nine were selections from adapted landraces, whereas six were developed by hybridization followed selection [5], and average yields of popular cultivars range from 1020 to 2016 kg ha⁻¹ [33]. In India, 24 cultivars have been released, of which seven were developed by hybridization followed by selection and the remaining by selection from landraces, with yields of 0.8–2.6 t ha⁻¹ (<http://www.aicrpsm.res.in/Releasevarieties.html>). In this study, we identified 18 accessions as promising for higher grain yield (1601 to 2334 kg ha⁻¹), with two of these (IPm 2661 and IPm 9) also having large seed size. These high-yielding accessions could be tested in multiple locations to assess their adaptation and yield potential, and could be released as cultivars.

Large variation was observed for Fe (41–73 mg kg⁻¹), Zn (26–47 mg kg⁻¹), Ca (91–241 mg kg⁻¹) and protein (11–19%) contents. The proso millet accessions had an average of 54 mg kg⁻¹ of Fe, 36 mg kg⁻¹ of Zn, 165 mg kg⁻¹ of Ca, and 14% of protein. On average, Fe, Zn and protein contents were higher than in the finger millet core collection (Fe 29.3 mg kg⁻¹, Zn 19.9 mg kg⁻¹, and protein 7.3%) [34], and Fe, protein and Ca contents were higher than in the foxtail millet core collection (Fe 49.8 mg kg⁻¹, protein 13.5% and Ca 145.8 mg kg⁻¹) [35]. Wang et al. [36] identified accessions with protein content >15% by screening 6515 germplasm accessions from 14 provinces of China. Proso millet accessions rich in two or more grain nutrients were identified, of which IPm 2875, originating in the Republic of Korea produced high grain yield (917 kg ha⁻¹). In general, the seed coat of proso millet is not readily removed by threshing and the grain requires seed processing machinery for dehulling, whereas the seed coat of IPm 2875 is readily removed by threshing, a useful and economically important trait. The seeds of IPm 2875 (without seed coat) had 48.8 mg kg⁻¹ Fe, 39.8 mg kg⁻¹ Zn, 213.1 mg kg⁻¹ Ca, and 16.4% protein. All the grain nutrient-rich accessions had significantly higher grain nutrients than the high-yielding accession IPm 9. Accessions IPm 2069, IPm 2076, and IPm 2537 were rich in all four grain nutrients. Further, the 10 most diverse pairs of accessions within sources for high grain yield and multiple grain nutrients, and between high-yielding and multiple-nutrient accessions, were identified and could be used in breeding programs with agronomically superior accessions. Negative correlations of grain nutritional contents with grain yield and positive correlations among grain nutrients were observed, suggesting that exploitation of hybridization-derived variation is the next step toward combining two or more grain nutrients and desirable agronomic traits with the goal of breeding high grain-yielding and nutrient-dense proso millet cultivars. Significant influences of genotype and season (except for peduncle length), and their interaction (except for basal tiller number, panicle exertion, and protein content) were noted. However, moderate to high heritability was observed for all the traits investigated including grain yield and grain nutrients, indicating that a large

fraction of variation was due to genetic effects. It could be useful to assess the stability of macro- and micronutrients across different soil types and soil fertility levels typical of the areas to which the cultivars are targeted. Knowledge of genotype \times environment interactions aids in designing suitable breeding and selection strategies to increase grain nutrients in edible portions of grain [37].

In general, average yields of accessions belonging to races *patentissimum* and *miliaceum* were high, whereas accessions of *ovatum* produced low grain yield. The high grain-yielding accessions identified belong to either *miliaceum* (13 accessions), *patentissimum* (3 accessions), or *contractum*, suggesting that evaluation of the full set of accessions of *patentissimum*, *miliaceum*, and *contractum* maintained in genebanks would reveal additional high grain-yielding accessions. The selected high grain-yielding accessions also had high grain nutrient contents (Fe, 44.9–61.4 mg kg⁻¹; Zn, 26.7–36.2 mg kg⁻¹; Ca, 91.1–148.2 mg kg⁻¹; protein 10.8% to 13.4%), though not significantly higher than the trial means. Accessions of races *ovatum* and *compactum* are potentially superior sources for high grain nutrients compared to other races, indicating the importance of these races for grain nutritional trait improvement.

5. Conclusions

Large variation was found in proso millet germplasm for morpho-agronomic and grain nutrient traits (Fe, Zn, Ca, and protein). Diversity assessment indicated that race *patentissimum* had high diversity and race *ovatum* low diversity. High divergence was observed between *patentissimum* and *ovatum*, and the lowest divergence between races *compactum* and *ovatum*. The diversity of proso millet was structured according to geographical region, country within region, and racial group. This study supports independent origins of proso millet in Europe and Asia, or the crop may also have originated by domestication within Asia and then spread westward across the Eurasian steppe. Trait-specific sources including 18 accessions for higher grain yield, 10 large-seeded accessions, and 26 accessions rich in multiple grain nutrients, and highly diverse pairs of accessions, were identified for potential use in proso millet improvement. This study provides valuable information to proso millet researchers, and the trait specific sources identified could be tested for their adaptation in diverse locations for grain yield and grain nutritional content stability, for direct release as cultivars, and could be used in breeding for developing high grain-yielding and nutrient-rich cultivars. Cultivation and consumption of proso millet would not only reduce micronutrient and protein malnutrition but also contribute to crop and diet diversification.

Proso millet researchers can obtain seed samples of these accessions from the ICRISAT genebank for research purposes via a Standard Material Transfer Agreement.

Acknowledgments

The authors gratefully acknowledge the contributions of Mr. Shailesh K. Singh, Mr. Venu Gopal, and Mr. Thimma Reddy of

the ICRISAT Genebank, Patancheru, India in data collection and documentation.

Conflict of interest

The authors hereby state that there is no conflict of interest with regard to this manuscript.
